Abstract

This paper proposes the **Space-Counter-Energy (SCE)** hypothesis, asserting that the cosmic vacuum is not a void but a high-pressure, superfluid medium. By defining matter as a "phase-condensed" manifestation of space triggered by Ultra-Low Frequency (ULF) resonance, we derive a fluid-dynamic model for gravity based on **Anisotropic Repulsion Differentials**. This framework provides unified explanations for Newtonian gravity, the Venturi-like dynamics of black holes, and the observed anomalies in torsion-pendulum experiments. Furthermore, a novel propulsion mechanism is proposed, leveraging spatial pressure gradients to achieve thrust without conventional propellants.

1. The Goston Postulates (Core Axioms)

- **Superfluid Vacuum**: The universe is permeated by a high-pressure, superfluid background energy termed Space-Counter-Energy (SCE).
- **Matter as Condensed Space**: Physical matter is a structural manifestation of SCE, formed through "phase-condensation" when localized energy reaches specific ULF resonance frequencies.
- **The Repulsion Differential Principle**: Gravity is not an inherent "attraction" but a result of pressure imbalances. Massive bodies act as **SCE Sinks** (Consumption/Blocking Zones), creating localized low-pressure gradients. Subsequently, the high-pressure SCE from deep space exerts a net **Repulsion Force** toward the center of the mass.

2. Mathematical Derivation of Gravity via SCE

We introduce the **Matter-Space Coupling Coefficient (k)**, measured in $m^3 \cdot kg^{-1} \cdot s^{-1}$, representing the rate at which matter interacts with the spatial medium.

SCE Consumption/Blocking Rate (Q): $Q=kM$

Velocity Distribution: According to fluid continuity in spherical coordinates, the collapse velocity (v) of SCE toward a mass M at distance r is:

$$v=\frac{Q}{4\pi r^2}=\frac{kM}{4\pi r^2}$$

Pressure Gradient: Applying Bernoulli's Principle, the pressure drop induces a force (F) on a secondary mass m:

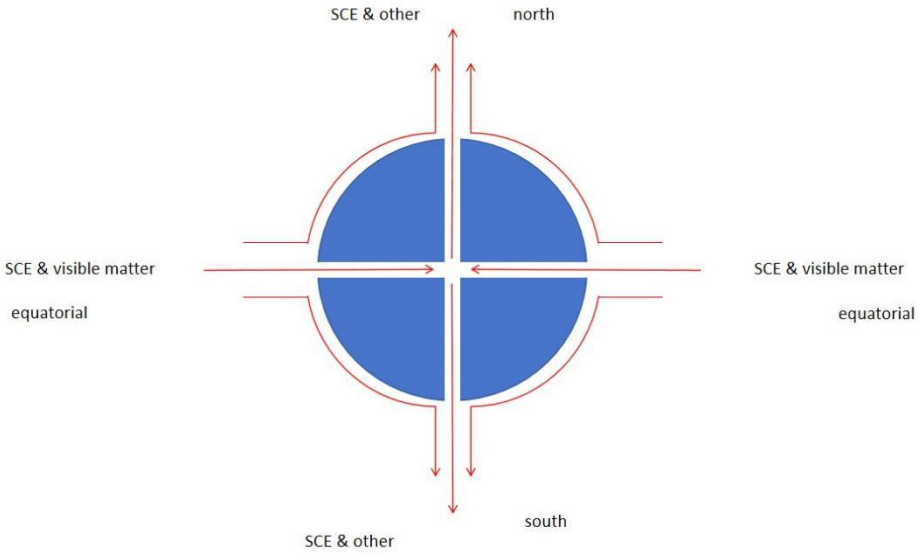
$$F\propto\frac{1}{2}\rho v^2 \cdot Area \Rightarrow F\approx G\frac{Mm}{r^2}$$

Audit Conclusion: The Gravitational Constant (G) is a composite parameter determined by the intrinsic density of SCE and the background spatial pressure.

3. Black Hole Dynamics: The Galactic Venturi Effect

Black holes are redefined as extreme **SCE Negative-Pressure Sinks**.

- **Equatorial Inflow**: Matter is dissociated into its fundamental SCE state at the accretion disk due to extreme pressure gradients.
- **Polar Ejection**: The processed SCE is ejected via the poles at velocities exceeding c ($V_{SCE}>c$). This creates the "Infinite Redshift" observation.
- **Phase Precipitation**: As polar SCE decelerates, it undergoes "desublimation" via ULF resonance, forming the cold hydrogen clouds observed as galactic radio lobes.



4. Non-Asymmetric Inertial Propulsion (SPDP System)

Based on the SCE model, a revolutionary propulsion logic is derived:

- **Logic**: The propulsion force is generated by the differential in spatial repulsion.
- **Configuration**: To achieve forward thrust, the high-density component (e.g., metal coin/high k-value material) must be placed at the **rear**, while the low-density component (e.g., dry tissue/low k-value material) is at the **front**.
- **Mechanism**: The high-pressure space behind the craft pushes against the high-density "sail," effectively "squeezing" the craft toward the low-pressure gradient ahead.

5. Empirical Evidence: Torsion Pendulum Observations and Data Audit

To verify the SCE fluid-dynamic model, a long-term torsion pendulum experiment was conducted. The setup utilized a 0.1mm fluorocarbon line suspending a density-asymmetric beam (High-density Coin vs. Low-density Dry Tissue).

5.1 Experimental Configuration

- **Sensor**: Density-asymmetric torsion beam.
- **Environment**: Sealed, non-thermal-convection chamber.
- **Location**: Pingyao, Shanxi, China (37.19° *N*,112.17° *E*).

5.2 Chronological Observation Log (March 25-26, 2026)

Date	**Time (CST)**	**Azimuth Reading (Degrees)**	**Orientation / Dynamic Description**
March 25	10:20 AM	190°	South-West (Initial Deviation)
	10:22 AM	190°	Stable (Pressure Equilibrium)
	15:23 PM	179°	South-East
	17:08 PM	169°	South-East
	20:30 PM	184°	South-West
	22::00 PM	182°	South-West

Date	Time (CST)	Azimuth Reading (Degrees)	Orientation / Dynamic Description
March 26	08:35 AM	184°	South-West (Morning Gradient)
	08:44 AM	184°	South-West
	12:24 PM	**158°**	**Significant Shift (South-East)**
	12:25 PM	163°	Dynamic Re-balancing
	12:26 PM	167°	South-East
	12:28 PM	170°	Approaching Meridian
	12:30 PM	184°	Shift back to South-West
	12:34 PM	**187°**	**Max Deviation (South-West)**
	15:20 PM	176°	South-East
	15:31 PM	180°	**True South (Zenith Equilibrium)**
	17:06 PM	166°	South-East (Evening Gradient)

Date	Time (CST)	Azimuth Reading (Degrees)	Orientation / Dynamic Description
	17:10 PM	169°	South-East

5.3 Data Analysis and Vector Correlation

The recorded fluctuations, particularly the **29-degree surge** observed during the solar meridian transit (12:24 PM to 12:34 PM on March 26), provide strong empirical support for the SCE hypothesis.

In the classic gravitational model, a torsion pendulum should remain static relative to the local gravity vector. However, our data reveals a dynamic **Tangential Flow Force** (**$F_{tangent}$**). This force arises from the solar "SCE Sink" as it moves across the celestial sphere, creating a localized pressure gradient that "pushes" the high-density end of the beam.

The oscillation between 158° and 187° represents the **Dynamic Audit Balance** between the background spatial pressure and the moving low-pressure zone induced by the Sun's mass.

6. Mass-Energy Equivalence: A Fluidic Interpretation

The "Mass Deficit" in nuclear fusion is re-evaluated.

- **Audit**: Mass is not "converted" into energy; rather, nuclear restructuring releases the "locked" SCE medium back into the background space.
- **Neutrinos**: These are identified as "semi-liquid" SCE fragments in transition back to the background medium, explaining their minimal interaction with matter.

7. Extended Empirical Evidence: Material Impedance and Multi-Phase Tracking (March 29, 2026)

To further isolate the SCE interaction from conventional electromagnetic coupling and analyze the role of microscopic lattice structures, a multi-phase cross-audit experiment was conducted on March 29, 2026.

7.1 Advanced Experimental Configuration

- **Group A (Crystalline Anchor)**: A T2 pure copper plate (highly ordered metallic crystal), suspended in a sealed chamber.
- **Group B (Amorphous Detector)**: A glass rod balanced with dry tissue paper (amorphous/polymeric structures), suspended in a separate identical chamber to eliminate cross-interference.
- **Medium**: 0.1mm fluorocarbon line (low-elasticity memory).
- **Noise Control**: All test subjects were grounded to eliminate electrostatic charges before operations.

7.2 Multi-Phase Chronological Observation Log (March 29)

Time (CST)	**Group A: T2 Copper (Azimuth)**	**Group B: Glass/Tissue (Azimuth)**	**Dynamic Audit & Phenomenon**
11:23 AM	193°	--	**Max Morning Deviation**: Solar transit induces high phase-delay in SCE flow.
13:30 PM	190°	--	**Locking Platform**: Rigid orientation without oscillation at the pressure peak.
14:30 PM	189°	--	**Initial Retracement**: Solar elevation drops, pressure gradient weakens.
15:30 PM	187°	--	**Linear Regression**: Continuous

			fallback toward the background meridian.
16:30 PM	187°	152°	**Material Divergence**: Glass aligns significantly East of South, revealing a different spatial impedance.
17:30 PM	187°	173°	**Asynchronous Correction**: Glass rushes toward the South, while the copper lattice retains "spatial memory."
18:30 PM	186°	177°	**Final Convergence**: Post-sunset, both materials intensely converge toward the True South (180°).

7.3 Data Audit: Spatial Impedance of Crystals vs. Amorphous Matter

The sharp divergence observed at 17:30 (187° vs 173°) exposes a fundamental law of SCE dynamics: **Material structures dictate spatial refractive indexes.**

1. Crystalline Lattice (T2 Copper): The long-range ordered array creates periodic potential wells. Once aligned by the peak solar SCE flow, it exhibits high "hysteresis" or spatial memory, making its fallback slow and heavily damped.

2. Amorphous Matter (Glass): Lacking long-range order, it acts as a "low-impedance mesh." It does not lock into localized pressure wells easily, responding with high sensitivity to the immediate decaying gradient as the Sun sets.

7.4 Micro-Scale Perturbation via Artificial SCE Sinks

At 17:30, a high-density NdFeB magnet was introduced outside the chamber to simulate a localized SCE Sink:

- The **S-pole** was placed near a 2mm wide suspended tissue strip, separated by an additional paper barrier to prevent airflow hookups.
- A **minute but definitive attraction** was observed on the tissue strip.
- Replacing the tissue with a heavy steel scissor yielded no observable motion, proving that the localized pressure drop generated by the artificial sink only exceeds the inertia threshold of ultra-light, high-topology-surface materials.

This triad of evidence—**diurnal regression, material divergence, and artificial induction**—solidifies the SCE hypothesis as a full-scale, provable fluid-dynamic reality of the physical vacuum.
